#### Abstract

Thirty seven diverse chilli (Capsicum annuum) genotypes were studied for 22 growth, yield and fruit quality traits. Multivariate analysis grouped the genotypes into 7 clusters. Cluster IV was largest containing 14 genotypes. Inter cluster distance was maximum between cluster V and VII (248.09), and minimum between cluster I and II (57.80). Cluster VII was most heterogeneous (intra-cluster divergence value 191.25) and Cluster II was most homogeneous (30.25). Genotypes were also analyzed for peroxidase enzyme polymorphism using gel electrophoresis which resulted seven electrophoretic bands (Rf 0.19 to 0.59 ) and grouped the genotypes into 6 zymotypes. Zymotype $P_{4}$ included maximum (13) number of genotypes. Number of clusters in peroxidase and multivariate analysis were almost same but distribution of genotypes varied. $73 \%$ of total genotypes showed similar pattern of grouping suggesting that the two methods are complementary to each other and should be carried out simultaneously to determine genetic diversity more effectively. Considering variability and diversity analysis of the genotypes, CUCH-4 from Cluster-II (\& Zymotype-P ${ }_{2}$ ) and CUCH-31, CUCH-34 and CUCH-35 from Cluster-VII (\& Zymotype-P4) were identified as promising genotypes which can be used in further crop improvement programme.

Keywords: Capsicum, Chilli, Diversity, Multivariate analysis, Peroxidase analysis

## INTRODUCTION

Chilli is an important commercial crop cultivated exclusively in tropical and temperate zones of the world and grown on more than 1.5 million hectares worldwide (Anonymous., 2007). Chilli finds its place as vegetable, spice and condiment. It is useful in pharmaceuticals also. India is the largest producer, consumer and exporter of chili, which contribute around $25 \%$ of total world production. After India, China is the major producer of Chili in the world (Anonymous, 2012). However, productivity of chilli in India is almost half than that of China (Ali, 2006). Identification of a genotype better suited for a particular region as well as it's improvement in all aspects is of immediate task. Genetic improvement of any crop depends on magnitude of genetic variability and the extent of heritability of economically important characters. Critical assessment of nature and magnitude of variability in the germplasm stock is one of the important prerequisites for formulating effective breeding methods. The higher genetic distance between parents, the higher heterosis in progeny can be observed (Lahbib et al., 2012). Traditionally, characterization and variability evaluation of a genetic stock is done by a combination of morphological and agronomic traits. However, this approach is prone to environmental influences (Peeraullee
\& Ranghoo-Sanmukhiya, 2013). The isozyme markers have been useful in determining genetic relationships among closely related species and cultivars (Aniel Kumar et al., 2013). Although morphological traits and isozyme marker analysis have been used to distinguish cultivars, both systems have limitations, the first due to environmental effects (Bhat et al., 1992a,b) and the latter due to selection of markers. Isozyme electrophoresis is chosen for its relative simplicity because it provides direct visualization of gene products (Brewer and Sing, 1970) and potentially can provide a unique fingerprint for each genetically distinct clone (Lebot et al., 1991). In chili pepper such studies on isozymes are very limited (Gupta et al., 1997; Onus and Pickersgill, 2000; Barrera et al., 2005). Nitesh et al. (2010) reported varietal identification of chilli peppers by PPO isozyme profiles. However, in depth studies on polymorphism of isozyme for assessing intravarietal relationships in chilli peppers is very limited (Aniel Kumar, Subba Tata, 2013).
The present study was aimed at assessing 37 chilli genotypes based on 17 morphological and 5 biochemical traits, grouping of genetically similar genotypes and further verification of this diversity analysis using peroxidase isozyme polymorphism analysis through gel electrophoresis.

## MATERIALS AND METHODS

Field trial: The 37 chilli genotypes were collected from different locations as mentioned in Table-2 and evaluated for three consecutive years (2007-08, 2008-$09,2009-10$ ) following randomized block designs with three replications. Pre-soaked seeds of all the genotypes were sown in seedbed in the first week of November each year. 45 days old seedlings were transplanted in the main field in the individual plots with a spacing of $45 \mathrm{~cm} \times 45 \mathrm{~cm}$ ensuring 40 plants in each plot. Transplanting was done by $2^{\text {nd }}$ fortnight of December each year. Essential intercultural operations (weeding, staking, time bound irrigation, plant protection measures etc.) were carried out as and when required. Seventeen morphological and five biochemical traits were selected for study following descriptor of Capsicum (IPGRI, 1995).
Multivariate analysis: The genetic divergence was calculated following Mahalanobis $\mathrm{D}^{2}$ statistics (Mahalanobis, 1936). Multivariate analysis or $\mathrm{D}^{2}$ analysis is a method for grouping genetically similar germplasms. It has been observed that for varieties development programme, it is desirable to classify the germplasm on the basis of diversity of different characters and to make crosses between groups having maximum diversity (Narasimhayya and Venkatarao, 1974).
Peroxidase isozyme analysis: The analysis was conducted taking leaf extract of $2^{\text {nd }}$ or $3^{\text {rd }}$ leaf of 60 days old plant. 500 mg leaf sample was crushed in 2.5 ml phosphate buffer ( $\mathrm{pH} 6.8 ; \mathrm{K}_{2} \mathrm{HPO}_{4}$ solution -6.15 ml and $\mathrm{KH}_{2} \mathrm{PO}_{4}$ solution - 3.85 ml dissolved in 100 ml water) in a pre-chilled mortar \& pestle. The crude homogenate was centrifuged at $14,000 \mathrm{rpm}$ at $4^{\circ} \mathrm{C}$ for 20 minutes. The supernatant was transferred into fresh tubes and divided into two parts. One part was used for protein estimation.
Protein estimation: Dried test tubes, cleaned with distilled water and alcohol, were marked according to the sample accession numbers. One was marked as blank. In each test tube $10 \mu \mathrm{l}$ cold tissue extract, 990 $\mu l$ phosphate buffer and 5 ml G250 dye were added. In the blank, instead of tissue extract, $10 \mu \mathrm{l}$ distilled water was added. The mixtures turned deep blue in colour immediately. Sample and blank were taken in two different cuvates and absorbance was estimated using a spectrophotometer (Makeup Jasco, Model-V630) at 595 nm . Protein content in each sample was calculated as per absorbance values against standard curve prepared using standard protein (BSA).
Peroxidase analysis was conducted in polyacrylamide gel (PAGE) system. The tissue extracts were taken in required amount after calculating its protein content. Vertical electrophoresis unit was used to run the gel.
Gel preparation: Gel was prepared in a dark conical flask having 12.2 ml water, $10 \mathrm{ml} 30 \%$ Acrylamide mix, 7.5 ml Tris-HCl (pH 8.8), $300 \mu \mathrm{l} 10 \%$ APS and $20 \mu \mathrm{l}$ TEMED. It was $10 \%$ Tris-Glycine Polyacryla-
mide gel solution.
Electrophoresis: The gel was ready in 1 hr . The gel plate was placed in the tank after pouring the tank buffer (Tank buffer prepared with Tris ( 1.2 g ) and glycine $(5.8 \mathrm{~g})$ dissolved in 100 ml distilled water and the volume was made upto 200 ml and diluted 10 times). Now, $32 \mu 1$ of sample extract and $8 \mu \mathrm{l}$ Bromophenol blue dye were mixed and added carefully at the comb places at top of the gel. Then electrophoresis was carried out at 15 Amp . \& 150 volt, approximately for 5 hrs until bromophenol blue reached the gel end. The gel was stained for peroxidase.
Staining: Gel plates were taken out, the gel was separated carefully and it was dipped in staining solution ( 100 mg ortho-dianisidine dissolved in 1 ml of Acetic acid; 200 ml of water and 2 ml of $\mathrm{H}_{2} \mathrm{O}_{2}$ added to it) horizontally and kept in dark for 30 minutes with occasional shaking. The bands of peroxidase developed. After staining, the gel was washed with distilled water and photographed by a gel documentation system (Multidoc, UVP) for band identification and final calculation.
Band analysis: Isozyme banding patterns were analyzed on the basis of number and Relative front (Rf) values of the bands. The Rf value is the mobility of each band travelled from the origin divided by the migration of tracking dye (Powers et al., 1988). Similarity coefficient values of electrophoretic pattern of each enzyme were subjected to cluster analysis employing the unweighted pair group method using arithmetic averages (UPGMA). For cluster analysis, value ' 1 ' was put for the presence and ' 0 ' for absence of the band for each genotype. Zymotypes were used for clustering and the Euclidean distance method (Nourish, 1993) was used for the dissimilarity.

## RESULTS AND DISCUSSION

The present study aimed at determining the genetic divergence of the 37 genotypes employing 22 important characters pertaining to growth, fruit yield components, proximate compositions of leaf and fruit and per plant fruit yield (Table 1).
Multivariate analysis: Following $\mathrm{D}^{2}$ statistics 37 genotypes were meaningfully grouped into 7 clusters (Table 2). It was found that the clustering pattern was, in general, not related to geographic origin of the genotypes which was in conformity with the earlier findings of Murty and Arunachalam (1966), Varalakshmi and Babu (1991), Pandey and Dobhal (1993) and Sreelathakumary and Rajamony (2004). However, some genotypes having similar place of origin were grouped in the same cluster like CUCH-22 and CUCH-23 in Cluster IV. Hence, implication of geographical origin on genetic diversity may not altogether be ignored.
Cluster-IV was the largest containing 14 genotypes followed by cluster VII and II having 8 and 7 genotypes in each respectively. Rest four clusters (cluster-I,

III, V and VI) had two genotypes in each (Table 2). The intra-cluster divergence was highly variable ranging from 30.25 in cluster II to 191.25 in cluster VII (Table 3). So, it may be said that cluster II, having 7 genotypes, is the most homogeneous group and cluster
-VII with 8 genotypes is the most heterogeneous group. High heterogeneity was also observed in cluster -IV showing high intra-cluster divergence (184.46). Inter-cluster distance was maximum ( $\mathrm{D}^{2}$ value 248.09) between cluster V and VII, suggesting wide diversity

among the members of these clusters. Minimal distance was noted between cluster-I and II (57.80) VI (59.53), indicating proximate relationship among the genotypes included in these two clusters.
Cluster-VII emerged as unique because it had the highest mean values for maximum number of yield contributing characters viz., leaf width, fruit girth, number of fruits per plant, fresh fruit weight, dry fruit weight and total fruit yield per plant (Table 4). This cluster also showed highest mean values for physiological and fruit quality characters like total chlorophyll content in

Fig. 2. Zymogram of electrophoretic pattern of peroxidase isozyme of 37 genotypes.
green mature fruit, total carotenoid content in red ripe fruit and leaf phenol content. Cluster-I though showed highest mean value for the growth and yield related characters i.e. plant height, plant canopy width, leaf length, fruit length, fruit pedicel length and 100 seed weight, but registered as third highest for fruit yield per plant after cluster-II. High mean values for earliness with respect to seed germination, days to $50 \%$ flowering and days from fruit set to maturity were recorded in cluster-III, though this cluster failed to score substantially high mean values for other yield related traits and at the same time, recorded the lowest yield per plant. Moderate expression of all the characters were recorded in Cluster-IV and V. Cluster-VI recorded the highest mean value for two fruit quality traits i.e. ascorbic acid content and capsaicin content but mean fruit yield per plant of this cluster was very low.
Crosses involving parents belonging to most divergent clusters are expected to give maximum heterosis and create wide variability in genetic architecture. However, for a practical plant breeder, the objective is not only obtaining high heterosis but also to achieve high level of production within the shortest possible time. In the present study maximum distance exists between cluster-V \& cluster-VII. However, considering intercluster distance and other agronomic performances, crosses between the members of cluster-II and clusterVII might exhibit high heterosis and is also likely to produce new recombinants with desired traits.
Isozyme analysis (analysis through poly-morphic banding): Study on genetic diversity in terms of isozyme poly-morphism have been extensively utilized in different vegetable crops viz., brinjal (Ali et al., 2011), tomato (Gunaseelan et al., 2011; Evans and Allridge, 1965), potato (Beatriz et al., 2001), radish (Ivy et al., 2010), and field crops like cotton (Farooq and Sayyed, 1999), soybean (Buttery and Buzzel, 1968; Brim et al, 1969) etc. but in chili pepper, such studies on isozymes are very limited (Onus \& Pickersgill, 2000; Barrera et al., 2005; Nitesh et al., 2010).
In the present study, peroxidase electrophoretic banding, zymogram following electrophoretic banding pattern and zymotypes of the 37 genotypes have been presented in Figure $1 \& 2$ and in Table 5. A total of seven bands of peroxidase were obtained ranging from $\operatorname{Rf} 0.19$ to Rf 0.59 . The number of bands varied with the genotypes. It is apparent from the Figure-2 and Table-5 that the band with Rf value 0.41 appeared in all the genotypes ( $100 \%$ band frequency) while the band with Rf value 0.19 appeared in minimum (19) number of genotypes ( $51.25 \%$ band frequency). Only 23 genotypes showed the band with Rf value 0.44 ( $62.10 \%$ band frequency). Frequency of other 4 bands with $\operatorname{Rf}$ values $0.24,0.49,0.54$ and 0.59 was $97.30 \%$, however their appearance varied with the genotypes.
Similarity matrix values of 6 peroxidase banding pattern (Table 6) suggested that the Zymotypes $P_{1}$ and $P_{4} ; P_{4}$ and $\mathrm{P}_{3} ; \mathrm{P}_{4}$ and $\mathrm{P}_{5}$ were close to each other in similar intensity
(Similarity index value 0.857 ). The Zymotype $P_{6}$ was farthest from $\mathrm{P}_{5}$ (Similarity index 0.286 ) followed by $\mathrm{P}_{3}$ and $\mathrm{P}_{2}$ (Similarity index 0.333).
Distribution of the peroxidase bands grouped the 37 genotypes into 6 zymotypes (Table 7). The Zymotype $\mathrm{P}_{4}$ was having all the 7 bands and also maximum number of thirteen genotypes in it. Three Zymotypes ( $\mathrm{P}_{1}, \mathrm{P}_{3}$ and $\mathrm{P}_{5}$ ) were having 6 peroxidase bands, with variation in their banding pattern. Zymotype $\mathrm{P}_{1}$ was devoid of band with Rf value 0.44 and contained 4 genotypes in it. Zymotype $P_{3}$ containing 9 genotypes had all bands except band with Rf value 0.19 . Zymotype $\mathrm{P}_{5}$ containing 1 genotype was lacking the last band with Rf value 0.59 . Zymotype $\mathrm{P}_{2}$ having 9 genotypes in it, had 5 bands excluding 2 bands with Rf 0.19 and 0.40 . The last Zymotype $\mathrm{P}_{6}$ containing only one genotype had only 3 bands i.e. $\operatorname{Rf} 0.19, \operatorname{Rf} 0.41$ and $\operatorname{Rf} 0.59$.
Multivariate analysis and Isozyme analysis: It was clear from the present study that overall 7 clusters were formed with multivariate analysis employing 22 quantitative traits (Table 2) whereas 6 zymotypes were obtained with peroxidase isozyme analysis (Table 7). The number of clusters obtained by multivariate analysis and peroxidase isozyme analysis were almost same but the genotypes included in each individual cluster varied. Zymotype $P_{1}$ has been formed with 4 genotypes of Cluster II. Other members of Cluster II were grouped in Zymotype $\mathrm{P}_{2}$, along with some members from Cluster III, IV, VI and VII. This phenomenon may be due to the environmental influence for the expression of quantitative traits. Almost similar result was recorded by Singh et al. (2010) in blackgram in which 8 clusters were formed with quantitative traits analysis whereas 9 clusters were obtained with SDS-PAGE analysis of total seed storage protein.

## Conclusion

In the present study thirty seven genotypes of chilli were grouped into seven clusters and six zymotypes irrespective of their origin. From this study, it may be concluded that a wide range of variation for almost all the economically important traits are present in this crop. This implies a good possibility of breeding through hybridization programme or direct use of promosing genotypes as variety for successful chilli production. Distant parents are able to exert high heterosis. Considering this theme and variability and diversity analysis of the genotypes, $\mathrm{CUCH}-4$ from Cluster-II (\& Zymotype-P 2 ) and CUCH-31, CUCH-34 and CUCH-35 from Cluster-VII (\& Zymotype-P4) were identified as promising genotypes. Further genetic studies may also be carried out using two or more promising genotypes, either through diallel or by line $x$ tester analysis. It also emerged that $72.97 \%$ of the total genotypes (i.e. 27 genotypes; 6 from C-IV to $\mathrm{P}_{4}, 4$ each from C-II to $\mathrm{P}_{1}$ and C-IV to $\mathrm{P}_{3}, 3$ each from C-II to $\mathrm{P}_{2}, \mathrm{C}$-IV to $\mathrm{P}_{2}$ and C-VII to $\mathrm{P}_{4}, 2$ each from C-VII to $\mathrm{P}_{2}$ and $\mathrm{C}-\mathrm{VII}$ to $\mathrm{P}_{3}$ ) grouped almost similarly under both multivariate analysis and isozyme polymorphism. So, it can be said that these two methods of determining diversity are complemen-
tary to each other and should be carried out simultaneously to determine genetic diversity in a more authentic manner. It is pertaining to say that isozyme polymorphism for chili cultivars could be used for cultivar registration which could be helpful for chili breeders.
