Abstract: The present study was conducted in textile mill of Pali city with the objective to study the risk of cardiac and gastric problems in relation to shift work among male workers. The results showed significant difference between Body Mass Index ($\chi^2=14.2$, $p=0.0008$) and waist hip ratio ($\chi^2=5.2$, $p=0.0226$) of shift and non shift workers. Results on food intake showed comparatively more deficient daily intake of nutrients like fiber (7.21 g), $\beta$ carotene (1842.89 $\mu$g), and folic acid (99.03 $\mu$g) in shift workers with respect to recommended dietary allowances and an overconsumption of fats (37.72 g). Alcoholism ($\chi^2=17.3$, $p=0.0001$) and smoking habit ($\chi^2=14$, $p=0.0029$) was found to be significantly higher among shift workers. Comparatively higher segment of shift workers suffered from hypertension (56.0%), disturbed appetite (87.50%), stomach upsets (90.0%), nausea (88.50%), heartburn (85.0%) and breathlessness (34.0%). Shift workers also had higher mean levels of lipid profile fractions and relatively more subjects fell into the category of high risk (20.50%) of CVD. Longer duration of involvement in shift work also influenced the occurrence of gastric and cardiac problems like disturbed appetite ($\chi^2=9.96$, $p=0.0411$), stomach upsets ($\chi^2=9.73$, $p=0.0452$), stomach ache ($\chi^2=10.1$, $p=0.0389$), constipation ($\chi^2=9.88$, $p=0.0424$), dizziness (47.37%), breathlessness (50.0%) and swollen feet (44.74%). The study concludes that shift work affects food intake, BMI, WHR, BP, alcohol intake, smoking habits and lipid profile of the subjects, thus increasing the risk of health problems like cardiovascular and gastric diseases.

Keywords: CVD, Food Intake, Gastric Problems, Lipid Profile, Shift Work

INTRODUCTION

Industrialization has been recognized as the main solution to the problem of unemployment in developing countries like India, in recent years. There has been a steady increase in the number of persons employed in various factories, over the past few years. However, data on nutritional status of factory workers are lacking and thus more attention needs to be given to obtain data on the physical and nutritional status of different categories of workers in different income groups, their knowledge and practices regarding health and nutrition. Nutritional status, health status and occupational stress are distinct but interrelated factors. Any variation in one factor will affect other two factors (Sassoon, 2010).

Textile industry touches the lives of all people in one or the other ways. In Rajasthan state particularly, textile mills represent an important economic sector. In Pali district, with highest number of textile mills in the state, the work never stops. It is a round the clock operating sector where shift work is highly prevalent. According to National Sleep Foundation (2014), a shift worker is anyone who follows a work schedule that is outside of the typical "9 to 5" business day. In the past few decades the world has become increasingly dependent upon shift workers to meet the demands of globalization and our 24-hour society. Shift work has many varied forms and does not solely include night shift as is the common belief, but encompasses afternoon and evening shifts, nights, rotating shifts, on-call work and with the inclusion of regular dayshifts (Blachowicz and Letizia, 2006).

As per International Classifications of Sleep Disorders given by American Academy of Sleep Medicine (2014) shift workers are at increased risk for a variety of chronic illnesses such as heart disease and gastrointestinal diseases. Whether this is related to the fact that shift workers are awake and active during the night hours or because they tend to get fewer hours of sleep overall than traditional workers is not known. Shift-work seriously affects the health and well-being of millions of people worldwide, and the number of shift workers is constantly rising (currently approximately 20% of the workforce) (Juda et al., 2010). There is evidence in the scientific literature of adverse physiological and psychological effects of shift work, including disruption to biological rhythm, sleep disorders, health
MATERIALS AND METHODS

A sample size of total 400 textile mill male workers was selected through scattered purposive sampling technique which involves selecting members from the population to comprise a sample because they specifically meet some prescribed purpose of specific attributes of interest that address the purpose of a particular research problem under investigation. Purposive sampling is used primarily in causal-comparative (ex post facto) research where the researcher is interested in finding a possible cause-and-effect link between two variables, one of which has already occurred (Essays, 2013). Out of these 400 workers, 200 engaged in shift work and rest 200 from non-shift working category was chosen. Workers were selected using the following criteria-

Age between 20-50 years.
Minimum 2 years of work experience in shift system (for shift workers).
Free from any degenerative disease like cancer, diabetes, osteoporosis etc.
Willing to participate in the study.

A structured interview schedule was developed keeping in view of the information to be collected for the study from shift workers. Standard Shift work Index (SSI) developed by Barton et al. (1995) was used in the questionnaire to collect information regarding shift duration and type, health problems etc. The interview schedule for non shift workers was kept same as shift workers, with the only difference of omission of questions pertaining to shift work. Measurements and indices like height (Jelliffe, 1966), weight, waist circumference and hip circumference of the subjects were taken and desirable body weight, body mass index (BMI) and waist-hip ratio (WHR) were calculated. The height was measured using vertical anthropometer rod. A platform spring balance was used for measuring weight. BMI was calculated by dividing the absolute weight (Kg) with absolute height (m) squared. Desirable or correct body weight (DBW) of the subjects was calculated using the formula:

Desirable body weight (DBW) = height in cm – 100... (1)

Waist circumference was measured midway between the lower rib margin and the iliac crest. Hip circumference was measured at the point yielding maximum circumference over the buttocks. Measurements were taken by non-stretchable tape and their ratios were calculated using following formula:

\[ \text{WHR} = \frac{\text{Waist Circumference (cm)}}{\text{Hip Circumference (cm)}} \]

A dietary survey was conducted using 24 hours recall method for one day. The quantity of different food items consumed by the subjects were asked and then converted in terms of their raw ingredients. The nutrient intake was calculated using nutritive value given in food composition table (Gopalan et al., 2002). The intake of nutrients was compared with the RDA suggested by Indian Council of Medical Research (2010) for adult male.

Blood pressure was estimated by using Automatic Blood Pressure Monitor (Omron HEM 7132). B.P.of the subjects was compared according to categories given by JNC VIII classification (Bell et al., 2015) of hypertension. As per “The Risk Assessment Index for Cardiovascular Disease” given by Easwaran et al. (2001), scores were given to each of the information provided by the subjects. These scores were summed up and the subjects were categorized on the basis of total scores obtained, in low, medium or high risk category. From each risk group 20% of the subjects, who were willing to cooperate, were selected for the estimation of their lipid profile. Lipid profile covers serum cholesterol, serum triglyceride and lipoproteins i.e. high density lipoprotein (HDL), low density lipoprotein (LDL) and very low density lipoprotein (VLDL). Serum cholesterol, Serum triglyceride and high density lipoprotein (HDL) were estimated by enzymatic methods, using estimation kits of ERBA diagnostic limited. Additional parameters like low density lipoprotein and very low density lipoprotein were calculated by using following standard formulas:

\[ \text{VLDL-C} = \frac{\text{Triglyceride}}{5} \] ………………………………………(3)

\[ \text{LDL-C (mg/dl)} = \text{Total cholesterol} – (\text{HDL cholesterol} + \text{Triglyceride}/5) \] ………………………………………(4)

The data were statistically analyzed as per the objectives of the study. t- Test and chi square tests were applied to find out the statistically significant difference between the data of shift and non-shift workers.

RESULTS AND DISCUSSION

The average duration of shift work of the subjects was 13.86 years, with the subjects working in three shifts, viz. morning, day and night shift. The morning shift timings is 6:30 AM to 3:00 PM; day shift lasts from 3:00 PM to 11:30 PM and thereafter night shift starts from 11:30 PM and ends at 6:30 AM. The shift system in which the subjects worked was found to be of irregular type i.e. there was no roster. The subjects working in night shift for a particular time would then either be transferred to morning shift or day shift. The fixed roster of transferring night shift subjects to morning shift and then day shift was not followed. About 25.50 percent of shift working subjects wanted to give up shifts and work in a day time job whereas 37.0 percent refused to give up working in shifts as it provided them more time to work second jobs.

problems, diminished performance at work, job dissatisfaction, and social isolation (Admiet et al., 2008). The study was conducted with the objectivesto study the food intake, prevalence of cardiovascular and gastric problems in the workers and determine the impact of shift work over the risk of these problems among the subjects.

According to Health and Safety Authority (2012), there are many different types of shift work, with variations in shift duration, number of shifts, shift rotation, rest periods between shifts and days off. The design of a particular shift pattern is a science in itself and will depend on many factors including business needs and the type of work being undertaken.

Anthropometric measurements of the subjects: Data in Table 1 depicts that shift working subjects had higher weights, Body Mass Index and WHR than desirable levels as compared to non-shift working subjects who had more number of workers falling in normal categories of anthropometric measurements. As per the Asia Pacific classification of BMI (WHO, 2000), it was found that the percentage of shift workers falling into underweight (1.50%) and normal BMI category (22.0%) were lower than those of non-shift workers. However, in the higher weight categories, the picture changes as the number of overweight (36.50%) and obese (7.0%) shift workers were higher than the non-shift workers. Hence, the chi square test statistic in case of desirable body weight (11.9, p=0.0182), body mass index (14.2 p=0.0008) and waist hip ratio (5.2, p=0.0226) was found to be statistically significant based on α level of significance (0.05). Based on these results it was observed that shift work influenced the weight, BMI and WHR of the subjects. There can be many contributory factors like lack of exercise, higher intakes of tea and fried food items available during odd working hours, disrupted schedules etc. which can explain the higher weights in shift workers than non-shift workers. These results are in line with the findings of Devadarshini et al. (2011) in which higher difference was noticed in mean weight of the shift workers (73.67+ 9.92kg) in comparison to the day workers (67.52 + 8.32 kg), which was statistically significant. The mean BMI of the shift workers was 25.82 kg/m2 which was higher than that of day workers, 23.37 kg/m2 and this difference was statistically significant. Suwazono et al. (2008) also reported a significantly increased risk of ≥5% weight gain among shift compared to daytime workers. Tada et al. (2014) found that during rotating shift work, shorter sleep and more consumption of sugar sweetened beverages was observed, as a result there was an increase in BMI among shift workers.

Nutrient intake: As depicted in Fig. 1, it is clear that difference between the nutrient intakes among the groups, though low, the intakes of all major nutrients were higher in shift workers than day workers, with exceptions of fiber and β carotene. The results further indicated that diet of all the subjects was improper and deficient in one or more nutrients. The situation is most alarming in the intakes of fiber, β carotene and folic acid where it isn’t even half of the recommended levels. On the other hand, intake of fat exceeded the RDA in both groups, with shift working subjects’ intake being as high as 150.88 percent of RDA. It can be attributed to the higher waking hours of shift workers which resulted in higher consumption of fried foods
and tea. According to Atkinson et al. (2008), meal frequency is generally reduced but snacking is increased on the night shift. Unavailability of preferred foods in the workplace, a lack of time, and a reduced desire to eat at night explain these findings. ‘Normal’ eating habits with the family are also disrupted. The metabolic responses to food are also altered by shift work-mediated disruptions to sleep and circadian rhythms.

Bilici and NavruzVarli (2016) studied the nutritional status of nurses in turkey and found that the mean daily energy intake was higher for shift workers (1756±659 kcal) than for day workers (1694±431 kcal) (p>0.05). Shift workers’ carbohydrate intake (196.3±85.5 g and 185.9±54.7 g, respectively) and fat intake (respectively 79.5±29.5 g and 77.1±22.6 g) were higher while protein intake (57.6±21.6 g and 59.4±17.6 g, respectively) was lower than those of day workers. Except for the mean daily intake of calcium and sodium, the intakes of all minerals were higher in day workers than in shift workers.

**Alcohol intake and smoking habit:** Habit of alcohol intake (table 2) was found to be higher in shift workers as nearly 47.50 percent subjects consumed more than two pegs per day as compared to 29.0 percent in day workers. Non users of alcohol were considerably higher in non-shift workers (32.0%) than shift workers (18.0%). Like alcohol, smoking habit was also higher in shift working subjects with 41.50 percent subjects smoking five to ten bidis/cigarettes per day, followed by 36.0 percent smoking more than ten bidis/cigarettes per day. Non-shift working subjects had

comparatively lower smoking percentages. The chi square test statistic in case of alcoholism ($\chi^2=17.3$, $p=0.0001$) and smoking habit ($\chi^2=14.0$, $p=0.0029$) was found to be statistically significant based on $\alpha$ level of significance (0.05). Ramin et al. (2015) reported that among modifiable risk factors like BMI, higher daily caloric and caffeine intake and shorter sleep duration, night shift workers were also more likely to be smokers (7% vs. 5%) as compared to day workers. Wirth et al. (2014) had the findings in same line and reported higher prevalence of smoking habit, tobacco intake and unhealthy dietary practices. In a study by Asare-Anane et al. (2015) on cocoa processing company workers, it was found that 33.63 percent shift workers consumed alcohol as compared to 27.59 percent of non-shift workers. Puttonen (2010) also associated shift work with tobacco smoking, alcohol consumption and unhealthy dietary patterns. The systematic review by Frost et al. (2009) was based on 14 studies, of which six reported on smoking and found that it was generally more frequent among shift workers.

**Blood pressure and pulse rate:** Data pertaining to blood pressure (table 3) revealed that according to JNC VIII classification (Bell et al., 2015) majority of the subjects in non-shift working category (44.0%) had pre-hypertension with systolic blood pressure ranging from 120-139 mmHg and diastolic blood pressure ranging from 80-89 mmHg, whereas majority of the shift workers (49.0%) were stage I hypertensive as they had blood pressure between 140-159/90-99 mmHg. Only 10.0 percent of shift workers had normal blood pressure (<120/80 mmHg) as compared to the 17.0 percent of non-shift workers. Stage II hypertension was found in 7.0 percent of shift workers as compared to 4.0 percent of day workers. The chi square test statistic in case of blood pressure ($12.1$, $p=0.0023$) was found to be statistically significant based on $\alpha$ level of significance (0.05) whereas no significant difference was found in case of pulse rate. Based on these results it was observed that shift work influenced the blood pressure of the subjects. Similar outcomes were found in a study by Kvatra and Singh (2012) which was carried out to assess the physiological and psychological cost of work. The result revealed significant difference in physiological parameters i.e. blood pressure, heart rate and psychological parameters of the respondents denoting their stress and fatigue due to shift work.

**Gastrointestinal problems:** The major problems regarding GIT (Fig. 2) faced by the subjects on a regular basis were disturbed appetite and stomach...
upsets, which were found to be more prevalent among shift workers (43.50% and 44.50%) than non-shift workers (6.0% and 13.50%). Nausea and heartburn along with indigestion and constipation were sometimes faced by a large number of subjects, especially in shift workers (52.50%, 71.0%, 53.0% and 64.50%) than non-shift working group (13.0%, 60.50%, 59.30% and 28.0%). The gastric problems least experienced were stomach ache, bloated stomach and diarrhea. The chi square statistic in case of regular occurrence (31.8) of gastric problems among the subjects was found to be statistically significant (p=0.0002) based on α level of significance (0.05). A recent systematic review by Knutsson and Boggild (2010) of twenty peer reviewed epidemiological studies, reporting an association between shift work and gastrointestinal diseases, pointed out that four out of six studies showed a statistically significant association with digestive symptoms, five out of six with peptic ulcers, and two out of three with functional GI disorders.

Shift work has been implicated by Zimberg et al. (2012) with multiple health problems over the long term. Specifically there is a greater chance for developing nutritional and metabolic disorders like altered metabolism, insulin resistance, diabetes, obesity, peptic ulcers, dyslipidemias, metabolic syndrome and gastrointestinal disorders. Evidence has shown that over a 4 to 5-year period, in both male and female shift workers the risk of the development of metabolic syndrome is more than day time workers. As per Kora-decka (2010), disorders of normal digestive system functions and metabolism, such as diarrhea, constipation or heartburn, may occur frequently in night shift workers compared to day workers. They result from improper nutrition, in terms of both the food quality and the time of meal consumption. Irregular meal times interfere with the production of hormones, acids and enzymes necessary for food digestion, a diurnal function. Like other body rhythms, the digestive system is affected by a number of factors: such as gastrointestinal diseases, cardiovascular diseases, hypertension (p=0.021), and the feeling of fatigue (p=0.004). The results of this study indicated that shift working could be associated with physical complications such as gastrointestinal diseases, cardiovascular diseases, and disturbances in circadian rhythm. 

**Cardiac problems:** Breathlessness was found to be most prevalent on a regular basis (Fig. 3) among nearly a quarter of the shift working subjects (22.5%). Apart from this, dizziness was also more faced by shift workers sometimes (28.0%). Chest pain and swollen feet were least experienced cardiac problems for both groups. Fig. 3 also depicts that the cardiac problems are more prevalent among the shift workers than non-shift workers. The chi square statistic in case of regular occurrence of cardiac problems (7.92) among the subjects was found to be statistically significant (p=0.0477) based on α level of significance (0.05). In a study on Finnish middle-aged men by Wang et al. (2015), weekend shift work appeared to accelerate the formation of carotid atherosclerosis, at an even greater speed among men with preexisting CVD. Circadian disruption caused by shift work has been shown to affect a number of risk factors for developing CVD including blood pressure and blood lipids (De Backer, 2009). A number of studies have shown that shift work is associated with coronary heart disease (CHD) (Vyas et al., 2012), but the evidence on a causal relationship is limited. CHD and ischemic stroke have many common risk factors (O'Donnell et al., 2010), that to some extent have been associated with shift work.

**Categorization of the subjects on the basis of risk factors:** Fig. 4 shows that although majority of the subjects in both groups fell into low risk of CVD category, there was a marked difference in the distribution of shift and non-shift working subjects in the three risk groups. Comparatively more number of non-shift work subjects (67.50%) fell into low risk category than shift workers (48.50%), whereas in medium risk group, shift workers (31.0%) were higher than day workers (23.0%). High risk category had shift work subjects (20.50%) that were more than twice the number of non-shift work subjects (9.50%) in the same category. The chi square statistic in case of risk groups (16.6) was found to be statistically significant (p=0.0002) based on α level of significance (0.05). It proves that the distribution of subjects among high, medium and low risk categories was different and got influenced by shift work.

The study by Abbaszadeh et al. (2014) aimed to determine the prevalence of disorders associated with shift work among security staff in a refinery complex. The prevalence of health problems among the shift workers was greater than day workers. Meanwhile, there were significant differences between shift and day workers in terms of gastrointestinal distress (p=0.034), cardiovascular disease (p=0.028), hypertension (p=0.021), and the feeling of fatigue (p=0.004). The results of this study indicated that shift working could be associated with physical complications such as gastrointestinal diseases, cardiovascular diseases, and disturbances in circadian rhythm. 

**Lipid profile of selected subjects:** Data in table 4 shows significant difference in total cholesterol, High Density Lipoprotein (HDL-C) and Low Density Lipoprotein (LDL-C) levels of shift and non-shift workers. Mean levels of all lipid profile fractions were found to be higher in shift working subject except HDL-C which was found to be lower. As per ATP III classification (National Heart, Lung and Blood Institute, 2001), the mean total cholesterol levels in both the groups were found to be in desirable category (<200 mg/dl). Normal levels were recorded in case of mean triglycerides (<150 mg/dl) and HDL-C (40-60 mg/dl) in both the groups, however the mean LDL-C level of shift workers (40.47 mg/dl) was extremely close to the low category (<40 mg/dl). The mean levels of LDL-C were found to be falling in
Duration of shift work and cardiac problems: The problems like dizziness (47.37%), breathlessness (50.0%) and swollen feet (44.74%) were found to be much higher among the subjects involved in shift work (Fig. 8) for more than twenty years as compared to subjects occupied in non-shift work (Fig. 7) for the same duration. However, non-shift workers had higher prevalence of chest pain (36.58%) among subjects working for longest periods as compared to shift workers (31.57%).

Another trend worth noting is that problems like dizziness and breathlessness had comparatively early onsets in shift workers (by 2 to 5 years) and affected large number of subjects when compared to non-shift workers who had late onsets and lower number of subjects suffering from these problems. As per Tucker et al. (2012) participants who had been working on rotating shifts for more than 10 years were found to be more likely to exhibit symptoms of metabolic syndrome than participants with no exposure to any form of shift work, even after controlling for age and gender. According to Vetter et al. (2016), compared with women without a history of rotating night shift work, women who worked less than 5 years of shift work at baseline did not have a significantly increased CHD risk in age-adjusted analyses, but there was a significant association between longer durations of shift work and CHD risk. Longer time since quitting shift work was associated with decreased CHD risk among ever shift workers in the Nurses’ Health Survey 2 (P<.001 for trend).

In another study, the authors reported an association between lifetime exposure to shift work and unfavorable changes in autonomic cardiac control related to a decrease in parasympathetic modulation, indicating a higher level of cardiac stress. The same study also reported an association between lifetime exposure to shift work and CHD risk. Longer time since quitting shift work was associated with decreased CHD risk among ever shift workers in the Nurses’ Health Survey 2 (P<.001 for trend).

Conclusion
The present study revealed that majority of the shift workers were smokers, consumed alcohol, had deficient diet and were suffering from sleep related problems. The preference of fried and fatty foods over vegetables and fruits was also highly common amongst the shift working subjects. Furthermore, comparatively higher percentage of subjects involved in shift work...
was found to be at high and medium risk of cardiovascular diseases. High consumption of fatty foods, unhealthy habits like alcohol consumption and smoking contributed to the risk of CVD and GIT disorders among the subjects. The duration of shift work also depicted an adverse impact over the risk factors and led to early onsets of cardiac and gastric symptoms, the occurrence of which got more regularized with continuous involvement in shift work. Nutritional programs focusing on industrial workers should be organized so as to make them aware about the impact of shift work and the possible lifestyle modifications like regular exercise, low saturated fat intake, high fiber intake etc. to prevent the occurrence of CVD and GIT disorders.
